(Received 2 February 2008)

We re-analyse experiments on a foam sheared in a two-dimensional Couette geometry [Debrégeas *et al.*, Phys. Rev. Lett. **87**, 178305 (2001)]. We characterise the bubble deformation by a texture tensor. Our measurements are local in time: they show two regimes, one transient and one stationary. They provide both the average and fluctuations of the anisotropy. Measurements are also local in space: they show that both the deformation and the elastic contribution to the stress field do not localise, varying smoothly across the shear gap. We can thus describe the foam as a continuous medium with elastic properties.

1. Introduction

A liquid foam exhibits “complex” behaviour under stress: it is elastic for small deformation, plastic for large deformation, and flows at large deformation rates (Weaire & Hutzler 1999), (Jiang *et al.* 1999). It is a model for the study of complex fluids: its typical length scale permits direct observation. In particular, a foam with only one bubble layer (so-called “two-dimensional foam” (Weaire & Hutzler 1999)) is easy to image, and image analysis yields information on all the geometrical properties of the foam.

Recently, Debrégeas *et al.* (Debrégeas, Tabuteau & Di Meglio 2001) quasistatically sheared a fairly dry foam in a two-dimensional Couette geometry (Fig. 1). They studied the velocity field and showed that it localises in a shear band: its changes of value happen as a steep gradient on a layer much thinner than the gap, rather than over a long distance. It decreases exponentially across the gap $(r_1 - r_0)$, as $\exp[-(r - r_0)/d]$. Here r is the distance to the wheel center, r_0 the radius of the inner wheel, r_1 the radius of the outer wheel, and $d \ll (r_1 - r_0)$ is a characteristic length comparable to one bubble diameter. Such shear-banding has been explained and numerically simulated by the combination of frozen disorder, elastic behaviour at low deformation, and local discrete bubble rearrangements, leading to an instability more likely to occur at the inner side where fluctuations are larger (Kabla & Debrégeas 2003).

What dominates the macroscopic behaviour of the material: averages or fluctuations?

FIGURE 1. Run 1 (transient regime): foam under steady quasistatic shear in a Couette geometry. Pictures of the foam correspond to different values of applied shear strain γ : (a) 0, immediately after switching from counter-clockwise to clockwise rotation; (b) 0.15; (c) 0.5, when the inner boxes have reached the yield strain (see Fig. 5); and (d) 7.6, well into the stationary regime. The cross-component $r\theta$ of the texture tensor, defined in eq. (3.11), is positive (a), zero (b), negative (c), and stationary (d).

This question is important in the rheology of foams, as well as in other disordered materials. Briefly, if the signature of fluctuations averages out at large scales, a “thermodynamical limit” exists in which the average dominates; a constitutive equation relating the stress and strain fields can then describe the material as a continuous medium (like a solid or a liquid). If the fluctuations have the same order of magnitude as the average at all scales, they can dominate the physical behaviour, which need not correspond to any continuous medium. Whenever the fluctuations dominate, we can ask whether they correlate (leading to large stress drops) or have a white spectrum. The answer need not be the same for different materials (say, foam and granular materials) nor for different quantities (say, velocity and deformation).

Similarly, the existence and origin of localisation raise different questions: the effect of boundary conditions, the respective roles of strain and strain rate, the precise role of fluctuations, the differences between various (disordered) materials, the distinction

between sharp (Coussot *et al.* 2002) or exponential (Debrégeas, Tabuteau & Di Meglio 2001) decreases, the dimension of space (2D or 3D), and even the field itself (velocity or deformation). We would like to extract additional physical information, beyond the velocity field.

Most suggestions to quantify statistically the anisotropy and the deformation of the internal structure of the foam, that is, the bubble wall network, are based on scalar quantities (Elias *et al.* 1999). Since the deformation encompasses information on both anisotropy and orientation, it is actually a tensor (Landau & Lifschitz 1986), (Alexander 1998). Recent suggestions of possible tensorial descriptions based on bubble details are promising (Reinelt & Kraynik 2000), (Kraynik, Reinelt & van Swol 2003), (Ball & Blumenfeld 2002), (Blumenfeld 2004). Here, we use the “texture tensor” (eq. 3.11), which has the following advantages (Aubouy *et al.* 2003): (i) it is purely geometrical, independent of stresses and forces; (ii) it applies to both small and large numbers of bubbles; (iii) it is local in time and space (Jiang *et al.* 2000), so it can characterise a sub-region of the foam; (iv) it applies to disordered or ordered, 2D or 3D materials, in elastic, plastic or fluid regimes.

The plan of this paper is as follows. Section (2) reviews the original experimental set-up, and our image analysis protocol. The theoretical section (3) reviews the definitions and measurements of stress, texture and strain tensors; it can be read separately. The next section (4) presents our analyses of experiments. The first (section 4.1), resolved in both time and space, studies the transient regime before a stationary flow is established. The second (section 4.2), resolved in space but averaged in time, shows that in stationary flow, both the bubble anisotropy and the elastic contribution to the deviatoric stress field vary smoothly across the Couette gap; they do not localise near the inner rotating wheel. The third (section 4.3), again resolved in time, shows that in stationary flow the fluctuations are larger near the inner wheel. In section (5), we discuss whether we can describe the foam as a continuous medium with elastic properties.

2. Materials and Methods

2.1. Experiments

Georges Debrégeas generously provided experimental data obtained in two different runs. For experimental details see Ref. (Debrégeas, Tabuteau & Di Meglio 2001). Briefly, the set-up consists of an inner shearing wheel and an outer fixed one, with no-slip conditions due to tooth-shaped boundaries (tooth depth: radius 1.2 mm). The foam is confined between two transparent plates separated by $h = 2$ mm spacers (Fig. 2(d)); this foam thickness is smaller than the distance between bubble centers (see below), enforcing a single layer of bubbles (Cox, Weaire & Vaz 2002). The fluid fraction, measured by the weight of water introduced in the cell, is $\Phi = 5.2\%$. The bubble size dispersity is $\sim 30\%$, enough to prevent crystallisation. Coarsening and size sorting under shear are negligible during the experiment. A CCD digital camera records the position and the shape of the bubbles.

The inner wheel rotates slowly enough ($V_{wheel} = 0.25$ mm.s⁻¹) that the flow is well in quasistatic regime: the foam passes through a succession of equilibrium states. All averaged static physical quantities, like the elastic strain or stress, remain the same if the applied shear rate $V_{wheel}/(r_1 - r_0)$ varies. Kinetic quantities, like the velocity field, the rate of T1s, and the input power and dissipation, scale as the shear rate. This scaling is typical of solid-like friction (only at higher velocity does the foam exhibit a fluid-like friction, when the input power and dissipation scale like the square of the shear rate). As

required for comparison to other experiments, we thus express all results as a function of the total applied shear strain:

$$\gamma = \frac{V_{wheel} t}{r_1 - r_0}. \quad (2.1)$$

Note that γ is proportional to time t , not to the local shear in each box.

Run 1 (unpublished data) contains a transient regime. To prepare the foam, the inner disc is rotated counter-clockwise, until a stationary regime is reached. Then, at an arbitrary time, chosen as the origin ($t = \gamma = 0$), the shear direction is switched to clockwise (Fig. 1), the experiment begins and 500 pictures are recorded. The $r\theta$ components of the deformation thus switch from positive to negative (Fig. 3). Each picture shows 200 bubbles, in an angular sector of the experimental cell (Fig. 1). The average distance between the centres of mass of neighbouring bubbles is 3.0 mm, with a standard deviation of ± 0.5 mm, corresponding to a mean bubble wall length of $\langle \ell \rangle = 1.7$ mm. The internal radius is $r_0 = 71$ mm (same for both runs) and the external radius is $r_1 = 112$ mm (different for each run). Thus $\gamma = 1$ corresponds to a wheel displacement of $V_{wheel} t = r_1 - r_0 = 41$ mm: *i.e.* 15-20 bubble diameters.

Run 2 (published in Ref. (Debrégeas, Tabuteau & Di Meglio 2001)) focusses on the stationary regime. The preparatory rotation is clockwise. Then, at an arbitrary time, chosen as the origin ($t = \gamma = 0$), it is switched to counter-clockwise (Fig. 2). Pictures are recorded only after a full 2π -turn, corresponding to $\gamma = 8$; the $r\theta$ components of the deformation are thus positive (Fig. 6). A quarter of the Couette cell is filmed, with 700 bubbles in each picture. To improve the statistics, the camera is then displaced to record successively the four quarters; 2000 pictures are obtained as four 500-images movies. Data are measured and averaged over the four quarters of the foam. The average distance between the centres of mass of neighbouring bubbles is 2.4 mm, with a standard deviation of ± 0.4 mm, corresponding to a mean bubble wall length of $\langle \ell \rangle = 1.4$ mm. The internal radius is $r_0 = 71$ mm (same for both runs) and the external radius is $r_1 = 122$ mm (different for each run). Thus $\gamma = 1$ corresponds to a wheel displacement of 51 mm: *i.e.* 20-25 bubbles diameters.

2.2. Image analysis

We analyse the images using a home-made extension module to the public software NIH-Image. We threshold the image, and skeletise the bubble walls to a one-pixel thickness. We identify the points where three walls meet (“vertices”). We replace each wall by the vector $\vec{\ell}$ linking its vertices (white lines in Fig. 2a, top right).

To respect the symmetry of the Couette cell, this wall vector $\vec{\ell}$ (Fig. 2b) is expressed in local polar coordinates (r, θ) (Fig. 2a). This neglects the variation of the polar referential between both its end points. This assumption is correct as long as $\ell \ll r$.

For the same reason, we choose equi-spaced orthoradial, circular boxes (Fig. 2a, top right) to divide the foam and measure the deformation using spatial averages to improve the statistics. In the quasistatic regime, the bubble deformation remains very small and barely visible by eye. After trying various box sizes, we choose 8 boxes as a compromise between the quality of the statistics and the level of visible details.

For Run 1, each box is $2.7\langle \ell \rangle$ wide, and box number i is at position $r_1^i = r_0 + [0.4 + 2.7(i - 0.5)]\langle \ell \rangle$. The number of bubbles in each box grows linearly, typically from 17 bubbles in the 1st box, to 32 in the 8th box.

For Run 2, $r_2^i = r_0 + [2.8 + 3.1(i - 0.5)]\langle \ell \rangle$. Due to the shape of the pictures (Fig. 2a), the number of bubbles first increases with i (from typically 105 bubbles in the 1st box), then decreases (to 41 in the 8th box).

FIGURE 2. Run 2 (stationary flow): image analysis and notations. (a) *Bottom left*: top view of the original experiment by Debrégeas *et al.* (Debrégeas, Tabuteau & Di Meglio 2001), rotating counter-clockwise. *Top right*: image analysis. The reconstructed network of vertices linked by vectors (white) and the boundaries of the 8 equi-spaced concentric circular boxes used as representative volume elements (RVE) for spatial analysis (black circular arcs) are superimposed on the snapshot of the experiment. We exclude the regions near both wheels, where the bubbles are not entirely visible. (b) We denote by $\vec{\ell}$ the vector linking both vertices of a given wall. (c) If one of these vertices is outside of the box (defined in (a), top right), we denote by $f \in [0, 1]$ the fraction of the bubble wall length inside the box; $f = 0$ if the wall is entirely outside, $f = 1$ if it is entirely inside. (d) Side-view sketch of a vertical bubble wall cross-section, between two horizontal glass plates.

3. Definitions and measurements of deviatoric elastic stress and strain

3.1. Capillary contribution to the stress

3.1.1. Theoretical definition

In fluid foams, the three main contributions to stress $\bar{\sigma}$ are the capillary term $\bar{\sigma}^{cap}$ due to the tension of the liquid walls, the pressure of the gas within each bubble, and the viscous dissipation. In what follows, the “deviatoric” part of the capillary stress refers to the traceless tensor, *i.e.* $\bar{\sigma}^{cap} - \text{Tr}(\bar{\sigma}^{cap})\bar{I}/2$, where $\bar{I}$ is the identity tensor in 2 dimensions. It consists in the shear stress $\sigma_{r\theta}^{cap}$ and the normal stress difference $\sigma_{rr}^{cap} - \sigma_{\theta\theta}^{cap}$.

In the extreme “wet foam” limit $\Phi \sim 1$, bubbles are well separated from each other. The capillary contribution in a representative volume element (RVE) V which contains

N bubbles with surface tension Γ is (Rosenkilde 1967), (Batchelor 1970):

$$\begin{aligned}\bar{\bar{\sigma}}^{cap} &= \frac{\Gamma}{V} \sum_{S \in V} \oint_S (\bar{\bar{I}} - \bar{\bar{n}} \otimes \bar{\bar{n}}) ds, \\ \sigma_{ij}^{cap} &= \Gamma \frac{N}{V} \left\langle \oint_S (\delta_{ij} - n_i n_j) ds \right\rangle_V.\end{aligned}\quad (3.1)$$

Here N/V is the density of bubbles; S is the surface of each bubble; $\bar{\bar{n}}$ is the unit vector normal to the surface element ds ; and $\langle \cdot \rangle_V$ is the average over bubbles in V .

In the other extreme, “dry foam” limit $\Phi \ll 1$, pairs of bubble surfaces merge into a film with surface tension 2Γ . The capillary contribution is (Khan & Armstrong 1986), (Khan & Armstrong 1987), (Reinelt & Kraynik 2000), (Kraynik, Reinelt & van Swol 2003):

$$\bar{\bar{\sigma}}^{cap} = \frac{2\Gamma}{NV} \oint_S (\bar{\bar{I}} - \bar{\bar{n}} \otimes \bar{\bar{n}}) ds + \mathcal{O}(\Phi^2). \quad (3.2)$$

The correction of order Φ^2 is a contribution of the integral over the surface S of its mean curvature (Mecke & Stoyan 2002). Since the mean curvature is mostly concentrated in bubble edges (“Plateau borders”), this contribution is physically equivalent to the recently identified line tension which affects the bubble edges (Kern & Weaire 2003), (G  minard *et al.* 2004).

3.1.2. Operational definition in two dimensions

A true 2D foam has an interesting property: at equilibrium, or in a quasistatic regime, the coarse-grained Laplacian of the pressure is zero (Graner *et al.* 2001), (Graner 2002). The small scale fluctuations of bubble pressures, according to bubble side numbers, average out to zero at large scales (Weaire & Hutzler 1999). In the present Couette geometry, where no large-scale pressure gradient exists, pressure does not vary significantly (Weaire *et al.* 2004). Hence, in-plane curvatures remain much smaller than the inverse of bubble sizes. They contribute to the stress through their algebraic average (not their second moment), which is small along any path within the foam: curvatures are counted positively if the path crosses the wall from the concave side (Graner 2002). They thus induce only a negligible correction to the deviatoric capillary stress, with respect to straight walls (Asipauskas *et al.* 2003).

However, adapting the above definition (eq. 3.2) to measure deviatoric capillary stress fields in bubble monolayers requires care. In the present case, the curvature radius in the third dimension, not visible in images, is smaller or equal to the half distance between plates (Fig. 2(d)). Its inverse, namely the curvature in the third dimension, is larger than the curvature visible in the image. This case is thus intermediate between two limiting bubble monolayers: bubble rafts, and Langmuir foams.

In bubble rafts, stress has already been measured, in a circular Couette geometry, by mechanical measurements of the force at the boundaries (Pratt & Dennin 2003), or indirectly by local measurements of bubble ellipticity (Ybert & di Meglio 2002). Since bubble top surfaces are curved (they are approximately spherical caps), direct local measurements of stress are difficult.

At the other extreme, Langmuir foams are one molecule thick: their aspect ratio is of the order of nanometers divided by centimeters, with no well-defined curvature in the third dimension. They are thus probably the closest approximation to a true 2D foam (as long as 3D viscosity effects remain negligible), and capillary stress fields can be measured as described below (eq. 3.5) (Courty *et al.* 2003).

In the present case, for a single layer of bubbles (Cox, Weaire & Vaz 2002) in the

quasistatic regime, the dry part of the film remains vertical (Fig. 2(d)). By symmetry, we can assume that the curvatures on both sides of a film are almost opposite, so that their effects almost cancel each other. We thus neglect the effect of curvature in the third dimension.

We simplify further eq. (3.2) using two approximations. First, although strictly speaking it applies to closed surfaces (complete surfaces of bubbles), we extend it to averages on open surfaces (walls between bubbles), assuming that any possible non-compensated term (due for instance to bubbles at the foam boundary) has a negligible contribution to the average (Kraynik, Reinelt & van Swol 2003). Second, on closed surfaces in 2D, the integral of the mean curvature only contributes a constant, so that the $\mathcal{O}(\Phi^2)$ term need not be considered here; in what follows, on open surfaces, we again neglect the contribution of possible non-compensated terms.

Finally, eq. (3.2) simplifies to an expression which has already been used (but not always justified) for various types of bubble monolayers (Weaire & Hutzler 1999), (Kabla & Debrégeas 2003), (Asipauskas *et al.* 2003), (Courty *et al.* 2003):

$$\overline{\overline{\sigma}}^{cap} = \frac{1}{V} \sum_{\vec{\ell}} f \left(\lambda \hat{e} \otimes \vec{\ell} \right). \quad (3.3)$$

Here (Fig. 2) the 2D RVE V is a surface area; the $\vec{\ell}$ s are the chords linking two connected vertices, approximating bubble walls; f is the fraction of the wall length contained in V ; $\hat{e} = \vec{\ell}/\ell$ is the unit vector tangent to $\vec{\ell}$. The line tension λ is equal to Γh multiplied by a geometric constant which depends on Φ (Fig. 2(d)): it varies from 2 for a dry foam (two flat interfaces of length h) to π for a wet foam (two half-circles of diameter h).

3.1.3. Comments on this definition

Eq. (3.3) is analogous to the expression for the elastic stress in a (2D or 3D) network with a density ρ of links $\vec{\ell}$ undergoing two-body interactions with tensions $\vec{\tau}$ (Kruyt 2003):

$$\overline{\overline{\sigma}}^{cap} = \rho \left\langle \vec{\tau} \otimes \vec{\ell} \right\rangle_V. \quad (3.4)$$

In the continuum limit, the average $\langle \cdot \rangle_V$ is the average of the wall probability distribution function, and this expression for the stress is exactly the same (see for instance ref. (Kruyt 2003) or the appendix of ref. (Aubouy *et al.* 2003)) as the classical definition based on the links crossing the boundaries of V (Landau & Lifschitz 1986). This equivalence validates *a posteriori* our application of eq. (3.2) to open surfaces. In practice, experimental data have a finite size: the number of links used in the calculation, and so the signal/noise ratio of the resulting measurement (Asipauskas *et al.* 2003), is much larger if we use all links in V , rather than only the links crossing its boundaries.

Eq. (3.4) shows that, in a network of points which interact through a pairwise potential, we can measure the stress from an image if we know the expression for the two-points force law $\vec{\tau} = \vec{\tau}(\vec{\ell})$ explicitly (for instance Lennard-Jones, or harmonic).

For quasistatic 2D foams (eq. 3.3), all tensions have the same modulus λ ; hence $\vec{\tau}(\vec{\ell}) = \lambda \hat{e}$. The image provides $\overline{\overline{\sigma}}^{cap}/\lambda$, which is enough for our purposes:

$$\begin{aligned} \frac{\overline{\overline{\sigma}}^{cap}}{\lambda} &= \rho \left\langle \hat{e} \otimes \vec{\ell} \right\rangle_V, \\ \frac{\sigma_{ij}^{cap}}{\lambda} &= \rho \left\langle \frac{\ell_i \ell_j}{\ell} \right\rangle_V. \end{aligned} \quad (3.5)$$

Here ρ is the area density of bubble walls: the number of bubble walls in V weighted by f , divided by V ; $\langle \cdot \rangle_V$ is the average over the walls in V , also weighted by f .

3.2. Status of the elastic strain tensor

3.2.1. Macroscopic definition of the elastic strain

A macroscopic definition of elastic strain (Macosko 1994), (Farahani & Naghdabadi 2000) is usually a function of the *deformation gradient* $\bar{\bar{F}}$:

$$\begin{aligned}\bar{\bar{F}} &= \left(\frac{\partial \vec{x}}{\partial \vec{x}^0} \right)^t = \left(\vec{\nabla} \vec{x} \right), \\ F_{ij} &= \frac{\partial x_i}{\partial x_j^0},\end{aligned}\tag{3.6}$$

where $\vec{x}$ is the current position of a point initially at position $\vec{x}^0$. This deformation gradient $\bar{\bar{F}}$ coincides with the identity $\bar{\bar{I}}$ in a solid translation, and has a determinant 1 in a volume-conserving transformation.

From $\bar{\bar{F}}$, we can define two symmetric tensors $\bar{\bar{U}}$ and $\bar{\bar{V}}$ through a rotation $\bar{\bar{R}}$ (Phan-Thien 2002):

$$\bar{\bar{F}} = \bar{\bar{R}} \bar{\bar{U}} = \bar{\bar{V}} \bar{\bar{R}}.\tag{3.7}$$

They are called the *right* and *left stretch tensors*. They coincide with the identity $\bar{\bar{I}}$ in a solid transformation (translation and rotation), and also have a determinant 1 in a volume-conserving transformation.

In turn, they determine a *right* and a *left deformation tensors*, called the Finger tensor and the Cauchy-Green tensor, respectively (Phan-Thien 2002):

$$\begin{aligned}\bar{\bar{B}} &= \bar{\bar{F}} \bar{\bar{F}}^t = \bar{\bar{V}}^2, \\ \bar{\bar{C}} &= \bar{\bar{F}}^t \bar{\bar{F}} = \bar{\bar{U}}^2.\end{aligned}\tag{3.8}$$

They too are symmetric, coincide with the identity $\bar{\bar{I}}$ in a solid transformation (translation and rotation), and have a determinant 1 in a volume-conserving transformation.

Finally, a *strain measure tensor* $\bar{\bar{E}}$ is for instance equal to $(\bar{\bar{B}} - \bar{\bar{I}})/2$, $(\bar{\bar{C}} - \bar{\bar{I}})/2$, or more generally to one of the Seth-Hill strain measure tensors based on the successive powers of $\bar{\bar{U}}$ or $\bar{\bar{V}}$:

$$\begin{aligned}\bar{\bar{E}}^{(m)} &= \frac{\bar{\bar{U}}^m - \bar{\bar{I}}}{m}, \\ \text{or } \bar{\bar{E}}^{(m)} &= \frac{\bar{\bar{V}}^m - \bar{\bar{I}}}{m},\end{aligned}\tag{3.9}$$

where m is a positive or negative integer (Farahani & Naghdabadi 2000). They all tend towards the linear elasticity definition (the gradient of the displacement field) in the limit of infinitesimal transformation.

The particular case of $m = 0$ corresponds to the logarithm-based definition (Hoger 1987) and generalises the Hencky strain tensor (Tanner & Tanner 2003) to arbitrary deformations:

$$\begin{aligned}\bar{\bar{E}}^{(0)} &= \log \bar{\bar{U}} = \frac{1}{2} \log \bar{\bar{B}}, \\ \text{or } \bar{\bar{E}}^{(0)} &= \log \bar{\bar{V}} = \frac{1}{2} \log \bar{\bar{C}}.\end{aligned}\tag{3.10}$$

This *true strain tensor* $\overline{\overline{E}}^{(0)}$ correctly quantifies both volume-invariant deformations (which appear as traceless strain tensors) and dilations (which appear as the logarithm of the volume, as, for example, in gases).

Constitutive equations of a material, that is stress-strain relations, can use either of these tensors; some arguments favor right tensors (Farahani & Naghdabadi 2000), (Larson 1997) while other favor left ones (Macosko 1994).

3.2.2. Micromechanical definitions of elastic strain

A microscopic definition of elastic strain (Kruyt & Rothenburg 1996), (Liao *et al.* 1997), (Alexander 1998), (Ball & Blumenfeld 2002), (Blumenfeld 2004), (Kruyt 2003), (Goldhirsch & Goldenberg 2002), (Zimmerman 1999), (Aubouy *et al.* 2003) adopts a different point of view: it constructs the macroscopic elastic strain from the positions of individual “sites” (*i.e.* atoms, grains, or vertices of a network), just as stress is constructed from individual forces, see eq. (3.4).

For instance, Zimmerman considers elastic deformations of 2D or 3D ordered atomic crystals (Zimmerman 1999). He constructs separately the stress (from atomistic potentials) and the elastic strain (from displacements). He shows that, in the ordered cases he considers, his strain yields a continuum-mechanics limit identical to that derived from the Cauchy-Green tensor.

Kruyt (2003) expands the analysis he used in a series of papers with Rothenburg, which, for instance, predicted the elastic moduli of disordered or ordered 2D granular materials (Kruyt & Rothenburg 2002). He constructs separately the stress from individual forces (obeying equilibrium conditions) and the elastic strain from individual displacements (obeying geometric compatibility conditions) small enough to avoid rearrangements (Kruyt 2003).

Goldhirsch and Goldenberg (2002) rewrite elasticity theory on a microscopic basis, take the continuous limit, and show its compatibility with classical elasticity, including the energetics and conjugation relations (Goldhirsch & Goldenberg 2002). In particular, they show that their definition of elastic strain is better than those based, for instance, on fits of the displacements to a macroscopic strain field (Liao *et al.* 1997) and that, even for granular materials, microscopic fluctuations progressively average out when going to macroscopic scales.

3.3. Extension to plastic and fluid regimes

Macroscopic and micromechanic elastic strain tensors become difficult to define after the first topological rearrangement. They finally lose their meaning after a few rotations of the Couette-cell inner wheel, and mathematical singularities appear. This breakdown of formalism is counterintuitive; experimentally, the mechanical behaviors of elasto-plasto-viscous materials do not appear to change discontinuously.

We need to treat the (even large) elastic deformation, independently from the flow involving rearrangements of the connections between neighbouring sites (changes in network topology). The total applied shear strain decomposes into plastic and elastic strains. The plastic strain is much larger, since it increases linearly with time (its derivative, corresponding to the velocity gradient, is constant in steady flow). The elastic strain is much smaller: here, in steady flow, it remains constant; but it is physically important, because it characterises the current state of the foam.

We use below the approach of Aubouy *et al.* (2003), which consists in three steps. It first characterises the current state of the material by a “texture” (or “fabric”) tensor $\overline{\overline{M}}$, built from statistical averages over microscopic positions, which exists in all regimes. It

then defines a reference state characterised by a reference tensor $\overline{\overline{M}}_0$. It finally constructs the elastic strain by a comparison of both tensors. We now review these definitions.

3.3.1. Texture tensor

The pattern of the walls in a region of the foam can be statistically characterised by the local *texture tensor* $\overline{\overline{M}}$ (Aubouy *et al.* 2003). In 2D, it writes (again with averages weighted by f):

$$\begin{aligned}\overline{\overline{M}} &= \langle \vec{\ell} \otimes \vec{\ell} \rangle_V, \\ M_{ij} &= \langle \ell_i \ell_j \rangle_V = \left\langle \begin{pmatrix} \ell_r^2 & \ell_\theta \ell_r \\ \ell_r \ell_\theta & \ell_\theta^2 \end{pmatrix} \right\rangle_V.\end{aligned}\quad (3.11)$$

It accounts for the direction and length ℓ of the walls; however, since the symmetry $\vec{\ell} \rightarrow -\vec{\ell}$ does not affect the pattern, the orientation of $\vec{\ell}$ plays no role.

The diagonal components M_{rr} and $M_{\theta\theta}$ of this tensor are both of order $\langle \ell^2 \rangle$. Conversely, the off-diagonal component $M_{r\theta} = M_{\theta r}$ (the tensor is symmetric), and the difference $M_{rr} - M_{\theta\theta}$, together characterise the anisotropy: they are both much smaller than $\langle \ell^2 \rangle$. They vanish when the foam is isotropic; in which case $\overline{\overline{M}} = (\langle \ell^2 \rangle / 2) \overline{\overline{I}}$ is proportional to $\overline{\overline{I}}$, and only encodes the r.m.s. wall length. Hence the tensor $\overline{\overline{M}}$ has two strictly positive eigenvalues, also of order $\langle \ell^2 \rangle$, the larger being in the direction in which bubbles elongate. It thus quantifies the average size, as well as the anisotropy direction and amplitude, of the network consisting of the bubble vertices (Fig. 2a, top right). In a stationary regime, it is constant, as are all averaged physical quantities.

3.3.2. Reference state

At any time, the current state of the foam corresponds to a current reference state, namely the state that the foam reaches after relaxation (Porte, Berret & Harden 1997). This reference state defines the *reference texture tensor* $\overline{\overline{M}}_0$. It varies with time; but in a stationary regime, it is constant, as are all averaged physical quantities including $\overline{\overline{M}}$. The reference state is not necessarily equal to the initial state (Porte, Berret & Harden 1997).

In the present experiment, letting the inner wheel rotate back freely is difficult, so that in practice we do not have direct access to a reference state. But we do not need microscopical details to estimate $\overline{\overline{M}}_0$: it suffices to make a physical approximation on the average properties of the foam at rest. We chose below to assume that the reference state is statistically isotropic. We thus approximate $\overline{\overline{M}}_0$ by $M_0 \overline{\overline{I}}$, where the constant $M_0 = \text{Tr}(\overline{\overline{M}}_0) / 2$ is half the average over all boxes of the squared wall length. We implicitly assume that the volume is conserved, which should be correct in Couette flow. More precisely, to avoid overestimating M_0 due to bubble stretching, we take the average between $\langle \ell \rangle^2 / 2$ and $\langle \ell^2 \rangle / 2$; since here $\langle \ell \rangle = 1.40$ mm and $\sqrt{\langle \ell^2 \rangle} = 1.45$ mm, we take $M_0 = 1.0$ mm².

3.3.3. Elastic strain tensor

We can operationally measure the *statistical elastic strain tensor* $\overline{\overline{U}}$ in each box from (Aubouy *et al.* 2003):

$$\overline{\overline{U}}(\vec{r}) = \frac{\log \overline{\overline{M}}(\vec{r}) - \log \overline{\overline{M}}_0}{2}.\quad (3.12)$$

It obeys (Aubouy *et al.* 2003) the mathematical requirements for a strain tensor:

symmetry properties under translation, rotation and index permutation. It is always defined: $\log \overline{\overline{M}}$ is the tensor with the same eigenvectors as $\overline{\overline{M}}$, but with the logarithm of its (strictly positive) eigenvalues. It is the only dimensionless function of $\overline{\overline{M}}$ and $\overline{\overline{M}}_0$ which is always defined (there is no equivalent of the division for tensors, except when they commute).

It also obeys the physical requirements for an elastic strain tensor. It statistically quantifies the deformation reversibly stored in the present state of the material. Its differential $d\overline{\overline{U}}$ (and hence the elastic moduli for infinitesimal deformation around the current state) depends explicitly only on the current state.

Moreover, let us consider the case where the (small or large) deformation is elastic and affine. Then:

$$\begin{aligned}\vec{\ell} &= \overline{\overline{F}} \vec{\ell}_0, \\ \vec{\ell} \otimes \vec{\ell} &= \vec{\ell} \vec{\ell}^t = \overline{\overline{F}} \vec{\ell}_0 \vec{\ell}_0^t \overline{\overline{F}}^t = \overline{\overline{F}} \left(\vec{\ell}_0 \otimes \vec{\ell}_0 \right) \overline{\overline{F}}^t, \\ \overline{\overline{M}} &= \left\langle \vec{\ell} \otimes \vec{\ell} \right\rangle = \overline{\overline{F}} \left\langle \vec{\ell}_0 \otimes \vec{\ell}_0 \right\rangle \overline{\overline{F}}^t = \overline{\overline{F}} \overline{\overline{M}}_0 \overline{\overline{F}}^t.\end{aligned}\quad (3.13)$$

If we now assume that $\overline{\overline{M}}_0$ commutes with $\overline{\overline{F}}$, which is the case if for instance $\overline{\overline{M}}_0$ is isotropic, then $\overline{\overline{M}} = \overline{\overline{M}}_0 \overline{\overline{F}} \overline{\overline{F}}^t$. We then prove that $\overline{\overline{U}}$ coincides with the true strain (Hoger 1987), (Zimmerman 1999):

$$\overline{\overline{U}} = \frac{\log \overline{\overline{M}} - \log \overline{\overline{M}}_0}{2} = \frac{\log \left(\overline{\overline{M}}_0 \overline{\overline{F}} \overline{\overline{F}}^t \right) - \log \overline{\overline{M}}_0}{2} = \frac{1}{2} \log \left(\overline{\overline{F}} \overline{\overline{F}}^t \right) = \overline{\overline{E}}^{(0)}, \quad (3.14)$$

see eq. (3.10). The Finger tensor appears because we base our elastic description on a tensor, $\vec{\ell} \otimes \vec{\ell} = \vec{\ell} \vec{\ell}^t$. This contrast with classical elasticity, based on a scalar product $d\vec{x} \cdot d\vec{x} = d\vec{x}^t d\vec{x} = d\vec{x}_0^t \overline{\overline{F}}^t \overline{\overline{F}} d\vec{x}_0$, where the Cauchy-Green tensor appears (Phan-Thien 2002).

A specific feature of the quasistatic regime is that the deformation (and hence the elastic strain) remains small, barely visible by eye (Fig. 1), even for large applied shear strain (and hence large plastic strain). We thus assume, and check *a posteriori* (Fig. 7), that the components of $\overline{\overline{U}}$ are much smaller than one, so we approximate eq. (3.12) by its linearisation:

$$\overline{\overline{U}}(\vec{r}) \approx \frac{1}{2} \left(\frac{\overline{\overline{M}}(\vec{r})}{\overline{\overline{M}}_0} - \overline{\overline{I}} \right). \quad (3.15)$$

4. Results

4.1. Transient regime

All data in this section are taken from Run 1 (Fig. 1), which has two distinct regimes: a transient and a stationary flow (Fig. 3).

4.1.1. Texture tensor

In the *transient regime*, the average wall length does not change much, but the walls tend to align with the direction of the rotation (Fig. 1). Hence, it is mostly the cross-component $M_{r\theta}$ which correlates to the shear (Fig. 3). Since $\gamma = 0$ marks the change from clockwise to counter-clockwise shear, $M_{r\theta}$ decreases linearly and changes sign. The correlation with shear of both other components, if any, is of order of their fluctuations.

FIGURE 4. Run 1 (transient regime): cross component $U_{r\theta}$ versus the applied shear strain γ , for box 1: closed circles, box 3: closed squares, box 5: open triangles, and box 7: crosses. Since $\gamma = 0$ marks the reversal of the rotation (and not an initially unstrained state), we expect $U_{r\theta}$ to be zero when $\gamma = 0.15$, within experimental error (± 0.03). A linear fit of $U_{r\theta}$ versus γ yields the derivative $dU_{r\theta}/d\gamma$, plotted in Insert, where the line is a linear fit with zero intercept to $dU_{r\theta}/d\gamma$ versus $1/r^2$.

4.1.2. Elastic strain tensor

During the transient, no bubble rearrangement (neighbour swapping, also called “T1 processes”) is visible for $\gamma < 0.3$. This probably corresponds to the elastic regime (Höhler, Cohen-Addad & Hoballah 1997). The cross-component $U_{r\theta}$ varies linearly with γ , and a linear fit yields its derivative $dU_{r\theta}/d\gamma$ (Fig. 4). It varies smoothly with r , and a fit to r^{-2} yields the prefactor $(-1600 \pm 90) \langle \ell \rangle^2$.

It is interesting to compare $dU_{r\theta}/d\gamma$ with the expression which would be predicted by classical elasticity in a Couette geometry:

$$\frac{dU_{r\theta}}{d\gamma} = \frac{r_1^2 r_0}{r_1 + r_0} \frac{1}{r^2}. \quad (4.1)$$

The prefactor of eq. (4.1) is $(r_1^2 r_0)/[(r_1 + r_0)] = (-1680 \pm 80) \langle \ell \rangle^2$, where we have taken 1.2 mm (the depth of the teeth) as the uncertainty of the wheel radius. This agrees with the experimental prefactor of r^{-2} (Fig. 4).

4.1.3. Yield

The flow becomes *stationary* at a value γ_Y which we measure by determining the intersection between the transient build-up of $M_{r\theta}$ fitted by a straight line and the stationary plateau fitted by a horizontal line (Fig. 3). It would be interesting to determine whether γ_Y actually marks the onset of irreversibility in the stress-strain relation at macroscopic scale (plasticity).

We can at least observe on the movie (data not shown) the “T1” bubble rearrangements, which concern local topology. In the inner boxes, γ_Y correlates with the appear-

FIGURE 5. Run 1 (transient regime): variation of γ_Y versus box number. Data are from Fig. (3). The line is a linear fit.

ance of a large number of T1s. The first isolated T1s appear at values of γ between 0.26 and 0.32, of the same order of magnitude as, but significantly smaller than γ_Y . The outer boxes lack T1s, except once near $\gamma \sim 3$, well beyond γ_Y and in the stationary regime. Though γ_Y is well defined, it marks a saturation in the local shear strain applied to the bubbles, which probably oscillates and remains below the actual yield strain.

The value of γ_Y increases gradually from 0.35 for the inner box, to 0.55 for the outer box (Fig. 3). Within experimental error (± 0.03 , corresponding to ± 2 images), this variation is linear (Fig. 5). Explaining this variation of γ_Y with r would certainly help us to understand the yielding of foams (see section 5.2.2).

4.2. Stationary regime - average values

All data of this section are taken from Run 2 (Fig. 2), which allows us to improve our statistics, using temporal averages over the stationary flow.

4.2.1. Texture tensor

Fig. (6) plots the average M_{stat} of the instantaneous texture tensor $\overline{\overline{M}}$ in the stationary regime. We can now detect, not only the (small) anisotropy of the foam, $M_{r\theta}$, but also its small spatial variations.

$M_{r\theta}$ decreases across the gap: it is larger in the inner boxes than in the outer ones, reflecting the preferred orientation imposed by the shear. M_{rr} decreases, $M_{\theta\theta}$ increases, and $M_{rr} - M_{\theta\theta}$ changes sign; this sign-change is more difficult to understand (section 5.1.3).

4.2.2. Elastic strain

$U_{r\theta}$ does not localise near the inner wheel: it varies smoothly with the distance to the inner wheel. It decreases as $\sim 1/r^2$ (Fig. 7), as expected if the foam behaves like a continuous elastic medium, see eq. (4.1).

To compare to the transient regime in Run 1 (which has slightly different bubble and

FIGURE 6. Run 2 (stationary flow): texture tensor $\overline{\overline{M}}_{stat}$ versus box number. The components of $\overline{\overline{M}}$ (closed triangles: M_{rr} ; open squares: $M_{\theta\theta}$; closed circles: $M_{r\theta}$), again expressed in units of $\langle \ell^2 \rangle$, are averaged over the four quarters of the whole foam, and also over time (2000 pictures).

wheel diameters), we express the prefactor determined in Fig. (7) in the same units as in eq. (4.1):

$$\langle U_{r\theta} \rangle = \gamma_{el} \frac{r_1^2 r_0}{r_1 + r_0} \frac{1}{r^2}. \quad (4.2)$$

The prefactor is $\gamma_{el} = 0.171 \pm 0.003$, see section (5.2.2).

4.2.3. Deviatoric elastic stress

In the quasistatic regime, mechanical equilibrium implies that the elastic stress is divergence free. Hence we expect that its off-diagonal component, which reduces to the capillary contribution, varies as for a continuous elastic medium in a Couette geometry (Dennin 2004): $\sigma_{r\theta}^{cap} \sim \text{cst}/r^2$. Such r^{-2} dependence occurs experimentally (Fig. 8).

FIGURE 7. Run 2 (stationary flow): tensor $\bar{\bar{U}}$ versus box number. The components of $\bar{\bar{U}}$ (closed triangles: U_{rr} ; open squares: $U_{\theta\theta}$; closed circles: $U_{r\theta}$) are derived from the data in Fig. (6) through eq. (3.15), using the value $M_0 = 1.0 \text{ mm}^2$ (see section 3.3.2). The solid line is a best fit of $U_{r\theta}$ to a function cst/r^2 .

FIGURE 8. Run 2 (stationary flow): elastic stress tensor $\bar{\bar{\sigma}}^{cap}$ versus box number. The deviatoric components of $\bar{\bar{\sigma}}^{cap}$ (closed circles: shear stress $\sigma_{r\theta}^{cap}$; open squares: normal stress difference $\sigma_{rr}^{cap} - \sigma_{\theta\theta}^{cap}$) are derived from eq. (3.5) and expressed in units of $\lambda/\langle \ell \rangle$. The solid line is a best fit of $\sigma_{r\theta}^{cap}$ to a function cst/r^2 .

FIGURE 9. Run 2 (stationary flow): Hooke relation. The deviatoric part of the capillary stress $\overline{\sigma^{cap}}$, expressed in units of $\lambda/\langle\ell\rangle$, plotted *versus* the corresponding components of $\overline{U}$ (closed circles: $\sigma_{r\theta}^{cap}$ versus $U_{r\theta}$; open squares: $\sigma_{rr}^{cap} - \sigma_{\theta\theta}^{cap}$ versus $U_{rr} - U_{\theta\theta}$). Each data point comes from Figs. (7) and (8), *i.e.* it derives from averages at one position in the foam. The solid line is a linear fit through all points, slope $2\mu\langle\ell\rangle/\lambda = 1.17 \pm 0.04$.

Again, the spatial variation of $\sigma_{rr}^{cap} - \sigma_{\theta\theta}^{cap}$, which changes sign, is more difficult to understand (section 5.1.3).

4.2.4. Non-dimensional shear modulus

In elasticity, the stress and the deformation are conceptually independent quantities (see section 5.1.2). In a continuous medium, they correlate physically; their relation is the elastic part of the material's constitutive relation (Landau & Lifschitz 1986). Let us focus on the components we measure here, namely the deviatoric terms $rr - \theta\theta$ and $r\theta$. If the material is linear, the components of strain and stress are proportional to each other, the slope being twice the shear modulus μ . If the material is isotropic, $rr - \theta\theta$ and $r\theta$ play a similar role. In polar coordinates, the Hooke equations becomes:

$$\sigma_{r\theta}^{cap} = 2\mu U_{r\theta}, \quad (4.3)$$

$$(\sigma_{rr}^{cap} - \sigma_{\theta\theta}^{cap}) = 2\mu(U_{rr} - U_{\theta\theta}). \quad (4.4)$$

Fig. (9) indicates that, in the quasistatic regime, the foam indeed behaves like a continuous medium: the deviatoric part of the capillary stress $\overline{\sigma^{cap}}$ and of $\overline{U}$ correlate strongly, and details of the microstructure appear only through mesoscopic averages. Moreover, the foam is both isotropic and linear, with a shear modulus $\mu = (0.59 \pm 0.02)\lambda/\langle\ell\rangle$. With a smaller or a larger box size, we obtain the same value for μ with a larger error.

4.3. Permanent regime - temporal fluctuations

4.3.1. Time series of $\overline{M}$ in Run 1

The stationary flow results from a balance between the increase due to the applied shear strain and relaxation due to bubble rearrangements (Langer & Liu 1997). The texture tensor and the elastic strain fluctuate around their mean value.

In Run 1, the short-term fluctuations are much larger near the inner wheel (Fig. 3a), where shape deformations and bubble rearrangements are both larger (Debrégeas, Tabuteau & Di Meglio 2001), than near the outer wheel (Fig. 3b). Fig. (3) does not show any significant physical feature of the fluctuation statistics, *e.g.* abrupt, large-scale relaxations of deformations *via* correlated, large stress drops.

4.3.2. Histograms of increments in Run 2

We perform a more quantitative analysis on Run 2, at a small scale, namely between two successive images, corresponding to an increase of $d\gamma$ in the applied shear strain. The increment of the texture tensor is defined as $\overline{M}(\gamma + d\gamma) - \overline{M}(\gamma)$. The signature of “avalanche-like” events at such a small scale would be extremely large fluctuations and/or a large asymmetry between positive and negative increments.

We find no such signature. The increments are almost Gaussian (Fig. 10a-c). The width of the histograms decreases by a factor of 10 from inner to outer boxes (Fig. 10d): as we mentioned, most large fluctuations occur near the inner wheel. Only $M_{r\theta}$ displays a slight asymmetry between positive and negative increments (Fig. 10b), probably because this cross-component is increased by the applied shear strain and decreased by the anisotropy relaxation due to T1 events.

4.3.3. Temporal autocorrelations in Run 2

The rotation of the inner wheel does not perturb the foam near the outer wheel. In the outer boxes, the texture tensor thus decorrelates very slowly. Let us quantify this observation using the data of Run 2.

To analyse the fluctuations at all scales of the shear strain $\delta\gamma$, we calculate the temporal autocorrelation C_{MM} of the fluctuations:

$$C_{MM}(\delta\gamma) = \frac{\langle (M(\gamma) - M_{\text{stat}})(M(\gamma + \delta\gamma) - M_{\text{stat}}) \rangle}{\langle (M(\gamma) - M_{\text{stat}})^2 \rangle}, \quad (4.5)$$

where $M(\gamma)$ (resp: M_{stat}) is the instantaneous value (resp: the average over the stationary regime) of the texture tensor $\overline{M}$.

Fig. (11) displays a rapid initial decay in the correlation, followed by a slower decay, reflecting the destruction of the initial conditions (Durian 1997), (Lauridsen, Twardos & Dennin 2002), (Ybert & di Meglio 2002), (Pratt & Dennin 2003). An exponential fit at small $\delta\gamma$ yields the shear strain γ_{decorr} characterising the initial loss of correlation, especially quick for the cross component $M_{r\theta}$ (Fig. 12):

$$M_{r\theta} = \exp\left(-\frac{\delta\gamma}{\gamma_{\text{decorr}}}\right). \quad (4.6)$$

As we expect, the correlation decays much more quickly near the inner wheel, $\gamma_{\text{decorr}} \approx 1/30$, than near the outer one, $\gamma_{\text{decorr}} \approx 1$ (insert of Fig. 12). The decorrelation rate $\gamma_{\text{decorr}}^{-1}$ decreases exponentially with the distance from the inner wheel.

The fluctuations of the texture tensor are thus localised near the inner wheel, over a distance comparable to 4 bubble diameters. This localisation resembles that of the

FIGURE 10. Run 2 (stationary flow): statistics for the increments of the texture tensor $\overline{\overline{M}}$. (a) Histogram of increments of M_{rr} in box 1, again expressed in units of $\langle \ell^2 \rangle$. Solid line is a Gaussian with the same standard deviation and zero average. (b, c) The same for $M_{r\theta}$ and $M_{\theta\theta}$. (d) Standard deviation of increments of $\overline{\overline{M}}$ versus box number (closed triangles: M_{rr} ; open squares: $M_{\theta\theta}$; closed circles: $M_{r\theta}$). Since the fluctuations in box 8 are extremely small (see Fig. 3), the data are noisy: image filtering and thresholding would have been required to obtain a statistically significant value.

velocity field over 1 bubble diameter (Debrégeas, Tabuteau & Di Meglio 2001), and is probably the signature of the effect of T1s on the deformation (Dennin 2004).

5. Discussion

5.1. Discussion of the strain and stress

5.1.1. Measurement method of the stress

Let us discuss the contributions to the stress we do not measure.

The dissipation is probably dominated by the friction on both glass plates, which we expect to be much larger than the internal viscous stress (Cantat, Kern & Delannay

FIGURE 11. Run 2 (stationary flow): temporal autocorrelation C_{MM} of texture tensor $\overline{\overline{M}}$ (eq. 4.5), versus $\delta\gamma$, in boxes 1, 3, 5, 7 (closed triangles: M_{rr} ; open squares: $M_{\theta\theta}$; closed circles: $M_{r\theta}$). We recall that the total applied shear γ is proportional to time, not to the local shear in each box (eq. 2.1).

2004). Whatever its physical origin, it should on average balance the input power. It is thus never negligible, especially during the relaxation after each T1, see section (2.1). However, the results we present here, which concern only the elastic terms, do not require us to measure the dissipation.

We measure the deviatoric elastic stress using eq. (3.5), which is formally equivalent to the stress in a network where sites interact through a two-body force. Foams do not include only two-vertex interactions. Their stability is due to the pressure inside each bubble, which relates to the bubble volume. Hence pressure is a function of all wall curvatures and all the vertex positions. It is an n -body interaction, which we can decompose into two-point interactions in principle (Alexander 1998), but not really in practice.

It is not important here to measure the pressure inside bubbles, for the following reasons (Graner 2002). Since the pressure stress is isotropic, it does not contribute to the deviatoric elastic stress. Hence the shear modulus is independent of the pressure field. Finally, the compression modulus of a foam is typically that of an ideal gas, which scales

FIGURE 12. Run 2 (stationary flow): autocorrelation $C_{M_{r\theta}M_{r\theta}}$ of the cross-component $M_{r\theta}$. Box 1: *crossed boxes*, box 2: *open circles*, box 3: *closed squares*, box 4: *open triangles*, box 5: *closed triangles*, box 6: *closed circles*, box 7: *open squares*, box 8: *diamonds*. Insert: initial decorrelation rate $\gamma_{\text{decorr}}^{-1}$ for each box (eq. 4.6).

like the pressure inside bubbles $\sim 10^5$ Pa (multiplied by h , when expressed as a 2D compression modulus). This modulus is not very interesting and is much larger than the shear modulus of the foam, which is thus effectively incompressible (Weaire & Hutzler 1999).

The line tension is not known, but unimportant for our present purposes. The stress, and hence the shear modulus, are expressed in non-dimensional form, as required for comparison to other foams. A direct measurement of λ can complement the local image measurement when necessary, for instance to predict the actual force exerted by the flowing foam on an obstacle, or to validate eq. (3.5) by checking its agreement with an independent, macroscopic measurement of the force (Courty *et al.* 2003).

5.1.2. Difference between $\overline{\sigma}^{cap}$ and $\overline{M}$

Both $\overline{\sigma}^{cap}$ and $\overline{M}$ are measured from the same image, and their definitions (eqs. 3.5, 3.11) seem similar. However, they are really independent both physically and mathematically.

Physically, their significance and status are different. The value of $\overline{\sigma}^{cap}$ can be determined from image analysis only if the sites interact through a two-body force $\vec{\tau}$, and if we explicitly know the form of this force $\vec{\tau}(\vec{\ell})$ with respect to the distance between sites. The value of $\overline{\sigma}^{cap}$ is sensitive to physical forces: first, it doubles if the density of links doubles; second, it does not change if we cut a link in two by artificially introducing a new site at its middle; third, in foams, it formally depends on wall curvatures.

On the other hand, $\overline{M}$ is purely geometric. It is a characteristic of the pattern, in-

dependent of physical interactions; it can be defined and measured for various kinds of cellular patterns for which no $\vec{\tau}$ can be defined, including solid foams, and even grain boundaries in crystals (Durand, Weiss & Graner 2004). The value of $\overline{\overline{M}}$ is sensitive to the detailed network topology: first, it does not change if the density of walls doubles; second, it decreases if we cut a wall in two by artificially introducing a new vertex at its middle; third, in foams, it is insensitive to the (in-plane or out-of-plane) curvature of walls.

Mathematically, $\overline{\overline{\sigma}}^{cap}$ and $\overline{\overline{M}}$ are independent in all cases, except when $\vec{\tau} \propto \vec{\ell}$, *i.e.* a harmonic spring, with a length ℓ much greater than its length at equilibrium. For instance, writing the stress of an isolated polymer molecule in a shear solvent as $\vec{\ell} \otimes \vec{\ell}$ is legitimate (Bird, Armstrong & Hassager 1987). However, foams, for which $\tau = \text{const}$, fall in the general case where $\overline{\overline{\sigma}}^{cap}$ and $\overline{\overline{M}}$ are mathematically different averages. The difference is even more visible in a 3D foam, where $\overline{\overline{\sigma}}^{cap}$ is an integral over a surface (Batchelor 1970), while $\overline{\overline{M}}$ remains based on vectors (Aubouy *et al.* 2003).

Moreover, $\overline{\overline{M}}$ does not even need be defined on the vectors $\vec{\ell}$ linking neighbour vertices. Definitions other than eq. (3.11) could be acceptable in principle (Dollet *et al.* 2004). For instance, we could use the vector $\vec{g}$ which links the centers of mass of neighbouring bubbles, and construct $\overline{\overline{M}}$ as $\langle f \vec{g} \otimes \vec{g} \rangle$. This would apply to bubble rafts (Dennin 2004), granular materials (Kruyt 2003), or 3D foams (Kraynik, Reinelt & van Swol 2003). This would change both $\overline{\overline{M}}$ and $\overline{\overline{M}}_0$ by a multiplicative constant: the elastic strain $\overline{\overline{U}}$ (eqs. 3.12, 3.15), and hence the shear modulus μ (eq. 4.4) would almost not change.

We emphasise that $\overline{\overline{\sigma}}^{cap}$ and $\overline{\overline{U}}$ are also independent. They represent different averages of microscopic details, so we cannot express one as a function of the other (Kruyt 2003), (Goldhirsch & Goldenberg 2002), except empirically, through numerical simulations or physical approximations approximations (Kruyt 2003). The difference is even more visible at large deformations: the logarithmic term of eq. (3.12) deviates from the linear approximation when the maximum value of the elastic shear strain (0.15 in Fig. 7) reaches large values, *e.g.* 0.4 (Courty *et al.* 2003) or 0.6 (Asipauskas *et al.* 2003). There is no trivial relation between them, except in a regular pattern, where averages are replaced by exact identities; for instance, in the case of a honeycomb, their relation is exactly as expected (Dollet *et al.* 2004).

5.1.3. Sign of normal differences

The normal differences $M_{rr} - M_{\theta\theta}$ and $\sigma_{rr}^{cap} - \sigma_{\theta\theta}^{cap}$ change sign in the middle of the gap, between boxes 4 and 5 (Figs. 6, 7, 8).

Normal stresses appear in elastic solid (Poynting 1909) or granular (Bagnold 1941) materials sheared at constant volume (this is equivalent to “dilatancy”: volume increase under shear at constant pressure (Weaire & Hutzler 2003)). In complex fluids such as foams, these normal stresses exist but are difficult to measure (Khan, Schnepfer & Armstrong 1988) and to predict (Weaire & Hutzler 2003). Predictions and 2D simulations of their average are accurate: under steady shear, the pressure of a foam with fluid fraction $\Phi = 5\%$ increases by 15% (Weaire & Hutzler 2003). This is the order of magnitude of the spatial variations of M_{rr} and $M_{\theta\theta}$ (Fig. 6). We can not predict their anisotropy (hence the normal stress differences), but normal stresses due to dilatancy are a second-order effect in the strain (Larson 1997): they are likely smaller than the large value of $M_{rr} - M_{\theta\theta}$ we observe, and might be masked by dynamical effects due to bubble rearrangements. But we can imagine other explanations.

First, this change could reflect an initial anisotropy resulting from the procedure used to fill the cell with foam (Debrégeas, Tabuteau & Di Meglio 2001), which the preparatory

rotation does not suffice to relax in the outer boxes (Debrégeas, personal communication). The initial state is not necessarily a zero-stress state. More generally, trapped stresses make notoriously difficult to measure normal stress differences (Khan, Schnepfer & Armstrong 1988), and carefully relaxed simulations are more reliable (Kraynik, Reinelt & van Swol 2003). The present measurement is probably one of the first direct experimental ones, along with that of Ref. (Labiausse, Höhler & Cohen-Addad 2004).

Second, it could be an artefact due to our measurement method, which does not accounts for the out-of-plane curvature of bubble walls (in the third dimension). Since the foam is not perfectly dry, the sides of a wall can have slightly different curvatures, so that their contributions would not exactly cancel out.

Third, this change could arise from a deviation from axisymmetric Couette flow, due to a secondary recirculation with radial velocity components. A signature of the discrete and disordered nature of the material is the appearance of solid body rotation of bubble clusters. It results in vortices, generic for amorphous elastic materials, generated by the “backflow” of the non-affine displacements (Tanguy *et al.* 2002). Their lifetime is as short as the time the internal wheel takes to move one bubble diameter (Debrégeas, Tabuteau & Di Meglio 2001).

5.2. Discussion of the stationary flow

The present measurements clarify a few open debates.

5.2.1. To localise or not to localise?

The experimental set-up, the fluid fraction, the friction on the plates, and the boundary conditions at the wheel, are those of Ref. (Debrégeas, Tabuteau & Di Meglio 2001). How can the same data alternatively display and not display localisation?

There is no fundamental incompatibility: different fields have different spatial variations. Ref. (Debrégeas, Tabuteau & Di Meglio 2001) measures the velocity field, and the T1 rate; while we measure the elastic stress and strain fields. In a quasistatic regime, where the foam is almost always close to mechanical equilibrium, we expect the stress to vary smoothly across the gap, as observed here and in simulations (Kabla & Debrégeas 2003). The elastic strain, which correlates to the elastic stress, does not localise, although the plastic strain, which correlates to the velocity gradient, does.

5.2.2. Yield

The value of the yield strain and stress, characterised *e.g.* by the equality of the real and imaginary parts of the complex shear modulus (Höhler, Cohen-Addad & Asnacios 1999), is not completely understood yet. It generally depends on the shear rate (Coussot *et al.* 2002), (Rouyer *et al.* 2003), but not in the present quasistatic regime.

We expect that, to store a deformation γ_{el} , requires us to apply an equivalent shear strain γ_Y . Since Run 1 corresponds to an inversion from counter-clockwise to clockwise rotation, we expect that $\gamma_Y = 2\gamma_{el}$. We observe an excellent agreement in box 1, in which $\gamma_Y = 0.35 \pm 0.02$ (Fig. 3) and $\gamma_{el} = 0.171 \pm 0.003$ (Fig. (7) and eq. (4.2)). But $\gamma_Y \neq 2\gamma_{el}$ in other boxes, for larger γ_Y (Fig. 5). Thus the deformation stored in the foam changes with γ even above γ_Y . Kabla and Debrégeas reach the same conclusion: their simulations indicate that, after the foam yields, T1s localise in the shear band only after a certain delay time (Kabla & Debrégeas 2003).

5.2.3. Averages and fluctuations

Our data show that stress and strain have a well defined, physically meaningful average at the scale of a representative volume element, while their fluctuations remain small. A

coarse-grained shear modulus can be defined and measured, unlike *e.g.* in granular media, where the importance of fluctuations at large scales is still an open debate (Goldhirsch & Goldenberg 2004).

More precisely, the statistics of the texture tensor are nearly Gaussian. Visual inspection of the images confirms that T1s remain isolated. They correlate (Kabla & Debrégeas 2003), but over a very small space and time range, probably due to the experimental conditions: disordered foam, quasistatic regime, large dissipation due to top and bottom plates. We do not observe extremely large fluctuations, nor sudden relaxations of deformations and stress.

Averages seem to dominate the physics Fig. (3), but fluctuations too are important. For instance, the width of the histogram of the velocity or stress field fluctuations might constrain the velocity field, and explain why shear-banding occurs preferentially near the inner wheel, due to a feedback loop on which fluctuations grow (Kabla & Debrégeas 2003).

Both the average and fluctuations of T1 rate manifest themselves in the texture tensor. The signature of the average T1 rate is the existence of a stationary regime, where the decrease in deformation due to T1s balances the increase due to applied shear. The signature of T1 rate fluctuations is the exponential localisation of the texture tensor fluctuations.

5.2.4. Measurement of the shear modulus

Fig. (9) suggests a few remarks. First, the classical method to measure a shear modulus consists in increasingly deforming a sample, and measure the stress and strain in successive states. We use here another method (Asipauskas *et al.* 2003). Each point in Fig. (9) comes from a different region of the same foam. We thus observe different deformation states simultaneously from a single heterogeneous image. Averaging over successive images reduces noise (Asipauskas *et al.* 2003), but is not necessary (Courty *et al.* 2003), (Durand, Weiss & Graner 2004).

Second, when determining the constitutive relation for plastic materials, the elastic stress is classically plotted *versus* the total applied shear strain: see Refs. (Jiang *et al.* 1999), (Reinelt & Kraynik 2000), (Weaire & Hutzler 2003) to quote a few. Different applied strains correspond to the same stress. Here we observe a one to one correspondance between elastic stress and elastic strain (Fig. 9). The foam is elastic, although the plastic strain increases steadily, and the foam is well beyond the yield strain.

Third, although we do not know the value of λ , we can compare our non-dimensional measurement of shear modulus μ with published values. An ideal two-dimensional dry monodisperse foam, where bubbles form a regular honeycomb lattice (Princen 1983), (Khan & Armstrong 1986), (Weaire & Hutzler 1999), has a shear modulus $\mu_{hc} = \frac{\lambda}{\sqrt{3}\langle\ell\rangle} = 0.577\frac{\lambda}{\langle\ell\rangle}$. Our μ is slightly larger, probably due to disorder; here $\frac{\langle\ell^2\rangle}{\langle\ell\rangle^2} = 1.08$. The non-zero fluid fraction tends to decrease μ (Princen 1983), (Khan & Armstrong 1986), (Mason, Bibette, & Weitz 1995), (Weaire & Hutzler 2003). In a non-quasistatic, and more heterogeneous, stationary flow, either through a constriction or around an obstacle, a dry foam (fluid fraction much lower than 5%), even with a small bubble size dispersity $< 5\%$, displays a shear modulus 20% higher than μ_{hc} , due to the stretched bubble shape ($\frac{\langle\ell^2\rangle}{\langle\ell\rangle^2} = 1.22$ (Asipauskas *et al.* 2003)).

6. Conclusion

To summarise, we re-analyse the data generously provided by Georges Debrégeas on a foam sheared in a two-dimensional Couette geometry, with the velocity field localised near the inner wheel (Debrégeas, Tabuteau & Di Meglio 2001). Since the flow is quasistatic, the deformation of the bubbles is very small. We take advantage of the foam's invariance under rotation (and, in the stationary regime, of its time invariance) to average over many bubbles. We then measure the texture tensor of the foam, a general tool to quantify the deformation of 2D or 3D networks and cellular patterns (Aubouy *et al.* 2003).

For small applied shear strain, a transient regime has the cross-component of the texture tensor increase linearly with shear, with no bubble rearrangements ("T1"), and the foam seems to behave like a classical elastic, continuous medium. The only large scale manifestation of the discrete, cellular nature of the foam is that, in a mixture of two fluids (soap solution and air), the surface tension of bubble walls produces elastic behaviour and a shear modulus.

The deformation saturates first near the inner wheel, then gradually in more distant boxes, at an applied shear strain γ_Y . This onset of plastic behaviour correlates, but does not strictly coincide with the appearance of T1s.

The foam then enters a stationary regime, where the deformation increase due to shear and the relaxation due to T1s balance each other. The fluctuations of the texture tensor around its mean value remain small. Despite the T1s, the elastic behaviour of the foam again resembles that of a classical elastic, continuous medium. The maximum shear strain that the foam can sustain in the quasistatic regime is γ_{el} , compatible with the value of γ_Y . The strain and stress are highly correlated, even proportional to each other; the shear modulus is slightly higher than for a honeycomb with similar average bubble wall length. The deviatoric components of the elastic strain and stress tensors, as well as the texture tensor, do not localise. The only trace of localisation is the much quicker loss of correlation of the texture tensor fluctuations near the inner wheel.

Future studies aim at understanding the origin of the value of the yield strain, the change of sign in the normal stress and strain differences, the precise role of boundary conditions, and the relation to granular materials. They include the measures of pressure and dissipation, and the analytical calculation of the shear modulus.

Acknowledgments: We are extremely grateful to G. Debrégeas for providing us with many recordings of his published and unpublished experiments, and for detailed discussions. We would also like to thank M. Dennin, R. Höhler, A. Kabla, A. Kraynik, N. Kruyt, J. Scheibert for discussions, M. Aubouy, B. Dollet, F. Elias and J.A. Glazier for critical reading of the manuscript, O. Cardoso for help with image analysis. This work was partially supported by CNRS ATIP 0693.
